

HIGH-K GATE DIELECTRIC STACK PLASMA TREATMENT
TO ADJUST THRESHOLD VOLTAGE CHARACTERISTICS

FIELD OF THE INVENTION

001 The present invention relates generally to high-K CMOS transistor gate stack fabrication processes in micro-integrated circuit fabrication and more particularly, to a method of treating a gate structure including a high-K dielectric gate stack to improve the threshold Voltage behavior in a CMOS device.

BACKGROUND OF THE INVENTION

002 Fabrication of a metal-oxide-semiconductor (MOS) integrated circuit involves numerous processing steps. A gate oxide is typically formed from thermally grown silicon dioxide over a silicon substrate which is doped with either n-type or p-type dopants. For each MOS field effect transistor (MOSFET) being formed, a gate electrode is formed over the gate dielectric, and dopant impurities are then introduced into the semiconductor substrate to form source and drain regions. Many modern day semiconductor microelectronic fabrication processes form features having less than 0.25 micron critical dimensions, for example more recent devices include features sizes of less than 0.13 microns. As design rules decrease, the size of a

resulting transistor as well as transistor features, for example gate length, also decrease according to scaling relationships. As gate lengths decrease, the problem of current leakage, for example gate induced drain leakage (GIDL) becomes more severe, which is a problem for low power devices, requiring increased transistor off current.

003 In order to overcome this phenomenon, an increasing trend in semiconductor microelectronic device fabrication is to use high-K (high dielectric constant materials) in the gate dielectric stack to achieve an equivalent oxide thickness (EOT) with thicker high-K materials. Because of high tunneling currents, SiO₂ films thinner than about 20 Angstroms cannot be reliably used as gate dielectrics in CMOS devices. There are currently intense efforts to replace traditional SiO₂ gate dielectric films with high-K dielectric materials. A high dielectric constant allows a thicker gate dielectric to be formed which dramatically reduces tunneling current and consequently gate leakage current, thereby overcoming a severe limitation in the use of SiO₂ as the gate dielectric at smaller device critical dimensions.

004 There have been, however, difficulties in forming high-k gate dielectrics to achieve acceptable threshold Voltage behavior in CMOS devices. Frequently, a relatively large shift in flatband Voltage or equivalent threshold Voltage occurs when high-K dielectrics are used in a gate dielectric stack for both NMOS and PMOS devices. For example, hafnium oxide (e.g., HfO_2) when used in the gate dielectric stack exhibits a shift of from about 300 mV in NMOS devices and about 700 mV in PMOS devices compared to a conventional SiO_2 gate dielectric.

005 The presence of unwanted interfacial states is believed to contribute to flatband and threshold Voltage shifts. Several approaches, from treating the base oxide layer, to post deposition annealing of the high-K dielectric prior to polysilicon electrode layer deposition have been proposed. Proposed approaches so far have met with limited success, threshold Voltages still exhibiting large differences compared to normal or desired behavior achieved with conventional SiO_2 gate dielectrics. As a result, the integration of high-K gate dielectric stacks with acceptable electrical behavior including acceptable threshold Voltage behavior in low power CMOS devices remains a problem to be overcome.

006 Therefore it would be advantageous to develop an improved method for forming gate structures including high-K dielectric layer stacks in CMOS devices having improved electrical performance including threshold Voltage performance.

007 It is therefore an object of the invention to provide an improved method for forming gate structures including high-K dielectric layer stacks in CMOS devices having improved electrical performance including threshold Voltage performance, while overcoming other shortcomings and deficiencies of the prior art.

SUMMARY OF THE INVENTION

008 To achieve the foregoing and other objects, and in accordance with the purposes of the present invention, as embodied and broadly described herein, the present invention provides a method for treating a gate structure comprising a high-K gate dielectric stack to improve electric performance characteristics.

009 In a first embodiment, the method includes providing a gate dielectric layer stack including a binary oxide over a silicon substrate; forming a polysilicon layer over the gate dielectric layer stack; lithographically patterning and etching

to form a gate structure; and, carrying out at least one plasma treatment of the gate structure comprising a plasma source gas selected from the group consisting of H_2 , N_2 , O_2 , and NH_3 .

0010 These and other embodiments, aspects and features of the invention will be better understood from a detailed description of the preferred embodiments of the invention which are further described below in conjunction with the accompanying Figures.

BRIEF DESCRIPTION OF THE DRAWINGS

0011 Figure 1, is an exemplary CMOS device including a high-K dielectric stack formed according to an embodiment of the invention.

0012 Figures 2A-2C are cross sectional views of a portion of an exemplary gate structure including a multi-layer high-K dielectric layer stack at stages in manufacture according to an embodiment of the present invention.

0013 Figure 3A is a graphical representation of exemplary Capacitance-Voltage (CV) data taken of exemplary CMOS devices formed according to preferred embodiments contrasted with a processing method excluding embodiments of the present invention.

0014 Figure 3B is a graphical representation of exemplary flatband Voltage data derived from CV data taken of exemplary CMOS devices formed according to preferred embodiments contrasted with a processing method excluding embodiments of the present invention.

0015 Figure 4 is a process flow diagram including several embodiments of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

0016 Although the method of the present invention is explained with reference to the formation of an exemplary high-K gate dielectric stack, it will be appreciated that the method of the present invention may be used for the formation of high-K gate dielectrics for MOSFET devices as well as capacitor stacks in a micro-integrated circuit manufacturing process.

0017 Although the method of the present invention is explained with reference to the use of exemplary high-k gate dielectrics it will be appreciated that the method of the present invention may be adapted for the use of any high-k oxide, for example a binary oxide material in the formation of a gate dielectric. By the term high-k dielectric is meant a material that has a dielectric constant of greater than about 10. The term "substrate" is

defined to mean any semiconductor substrate material including conventional silicon semiconductor wafers.

0018 Referring to Figure 1 is shown a cross sectional schematic of an exemplary CMOS transistor having gate structure including a high-k dielectric gate stack region according to an embodiment of the present invention. Shown is semiconductor substrate 12, for example a silicon substrate including lightly doped regions e.g., 14A, source/drain regions, e.g., 14B and shallow trench isolation regions, e.g., 16 formed in the silicon substrate by conventional methods known in the art. The regions 14A and 14B are typically formed following the formation of the gate structure. The gate dielectric portion of the gate structure is formed of multiple layers including for example, an interfacial silicon dioxide layer 18A, high-K dielectric portion 18B. A polysilicon gate electrode portion 18C is formed over the gate dielectric portion. The gate structure is formed by conventional methods including photolithographic patterning and anisotropic etching steps following blanket deposition of the various layers including an uppermost polysilicon layer.

0019 Following gate structure formation a first ion implantation process is typically carried out to form LDD regions e.g., 14A in the silicon substrate. Sidewall spacers e.g., 20A,

are then formed including for example at least one of silicon oxide (e.g., SiO_2), silicon oxynitride (e.g., SiON), and silicon nitride (e.g., SiN) including multiple layered spacers by methods known in the art including conventional deposition and etchback processes. A second ion implantation process is then carried out to form the source/drain regions e.g., 14B in a self aligned ion implantation process where the sidewall spacers e.g., 20A act as an implantation mask to form N type or P type doping regions depending on whether a PMOS or NMOS type device is desired.

0020 Referring to Figure 2A is shown an expanded cross sectional side view of a portion of an exemplary gate stack region at stages in manufacture according to an embodiment of the present invention. In an exemplary embodiment, shown is semiconductor substrate 22, for example single crystalline silicon having (111) or (100) orientation. The substrate may also be a layered semiconductor substrate such as Si/SiGe or Si/SiO₂/Si. The substrate may be of the n or p-type and preferably includes several active regions, for example N or P doped regions forming active charge carrying regions forming a portion of a MOFSET device.

0021 Still referring to Figure 2A, in an exemplary embodiment of the present invention, in a first step the silicon substrate

22 is cleaned prior to formation of an overlying thermally grown SiO₂ interfacial layer 24, also referred to as a base oxide layer. For example, the silicon substrate is cleaned using standard cleaning 1 (SC-1) and/or standard cleaning-2 (SC-2) solutions, which may be individually or sequentially used cleaning solutions including mixtures of NH₄OH-H₂O₂-H₂O, and HCl-H₂O₂-H₂O, respectively.

0022 Still referring to Figure 2A, in one embodiment of the invention, following the silicon substrate cleaning process, an interfacial oxide (SiO₂) layer 24 is formed over the silicon substrate 20, preferably to a thickness of between about 5 Angstroms to about 30 Angstroms by a wet or dry thermal oxidation or chemical oxidation method. High temperature wet or dry thermal oxide growth methods are preferred due to a superior quality Si/SiO₂ interface.

0023 Referring to Figure 2B, at least one high-K dielectric layer e.g., 26 is then deposited over the interfacial oxide layer 22 by conventional methods. It will be appreciated that the interfacial oxide layer 24 may be optionally subjected to surface treatments including chemical, plasma and/or annealing treatments as are known in the art prior to high-K material deposition. It will additionally be appreciated that the high-K dielectric layer

or stack may also be deposited directly onto the silicon substrate; however an interfacial oxide layer e.g., 24 is preferably provided for high-K dielectric stability when using binary oxide high-K dielectrics such as hafnium oxide (HfO_2).

0024 The high-K dielectric layer or stack 26 may be deposited by conventional methods, including atomic layer chemical vapor deposition (ALCVD), laser ablation, and reactive DC sputtering. Preferred high-K dielectrics include binary metal oxides such as tantalum oxides (e.g., Ta_2O_5), titanium oxides, (e.g., TiO_2), hafnium oxides (e.g., HfO_2), yttrium oxides (e.g., Y_2O_3), lanthanum oxides (e.g., La_2O_3), zirconium oxides (e.g., ZrO_2), and silicates and aluminates thereof.

0025 The ALCVD deposition process preferably takes place with the wafer substrate heated from about 200 °C to about 400 °C. An ALCVD process is preferred since it gives superior interface and film qualities. For example, molecular layers are sequentially deposited including a molecular layer of metal precursor, for example a metal-organic precursor, followed by controlled dissociation and oxidation of the metal-organic molecular layer to form a portion of the high-k dielectric layer, the process being sequentially repeated to complete the formation of the high-K dielectric layer. It will be appreciated that other

processes such as MOCVD or PECVD using metal-organic precursors may be used as well, but are less preferred methods of deposition due to lower quality electrical properties.

0026 In a most preferred embodiment, the high-K dielectric material includes a single layer or stacked layers of hafnium oxide (e.g., HfO_2) deposited by an ALCVD method at less than about 300 °C, more preferably about 200 °C to minimize lattice mismatch. It will be appreciated that the thickness of the HfO_2 will vary depending on the equivalent oxide thickness (EOT) desired, for example between about 5 Angstroms and 30 Angstroms. For example, the HfO_2 layer thickness may vary between about 40 Angstroms and about 100 Angstroms. Following deposition of the high-K dielectric layer or layers the high-K dielectric may be subjected to one or more annealing treatments, preferably including at least one of nitrogen, hydrogen or oxygen at between about 550 °C and 900 °C.

0027 Referring to Figure 2C, following deposition of the high-K dielectric layer e.g., 26, a polysilicon layer is deposited by conventional methods, for example LPCVD at less than about 580 °C followed by conventional lithographic patterning and etching, preferably RIE and/or chemically dependent etching (CDE), to etch through a thickness of the polysilicon layer to form the

polysilicon gate electrode portion 28 and through a thickness portion of the HfO_2 layer e.g., 26 to form high-K gate dielectric portion 26B while leaving at least a portion of the interfacial oxide layer 24 covering the silicon substrate. The interfacial oxide layer portion advantageously serves to protect the silicon substrate 22 in the subsequent plasma treatment process.

0028 According to an aspect of the present invention, following the gate etching process, the process wafer including the gate structure is subjected to a plasma treatment process. The plasma treatment is preferably carried out at pressures between about 100 mTorr and about 10 Torr, more preferably between about 1 Torr and about 5 Torr. The plasma treatment preferably includes the plasma source gases H_2 , N_2 , O_2 , and NH_3 or mixtures thereof. More preferably the plasma source gas includes hydrogen or nitrogen or mixtures thereof. Most preferably, the plasma source gas is hydrogen, due to minimal plasma damage and more efficient thermally activated diffusion in a subsequent annealing process.

0029 The plasma treatment may include conventional plasma operating conditions and plasma reactors including for example, inductively coupled plasma source (ICP), parallel plate, electron cyclotron resonance (ECR), dual plasma source (DPS), and

magnetically enhanced configurations. More preferably, the plasma reactor includes a DPS source to allow for independent wafer biasing. Exemplary operating conditions include an RF power of between about 100 Watts and about 600 Watts and a wafer bias between about 0 Watts and about 300 Watts.

0030 Depending on the reactor configuration, for example a DPS reactor, the plasma treatment is carried out between about 10 minutes and about 60 minutes. Following the plasma treatment, preferably a post plasma treatment annealing process is carried out in an ambient including at least one of H_2 , N_2 , O_2 , and NH_3 , more preferably primarily a nitrogen (N_2) or hydrogen containing ambient in the case of a plasma treatment with H_2 , N_2 , and NH_3 . The annealing process is preferably carried out at a temperature between about 550 °C and about 750 °C for about 5 minutes to about 30 minutes. It will be appreciated that the annealing process may be carried out in-situ following the plasma treatment, or may be carried out ex-situ in a separate single wafer treatment tool or in a batch wafer annealing process in a conventional furnace.

0031 It has been found according to preferred embodiments of the present invention that the plasma treatment of the gate structure including the polysilicon gate electrode and high-K

dielectric stack sidewall portions, followed by a post plasma treatment anneal gives the best results in advantageously adjusting the flatband Voltage, and consequently the threshold Voltage, such that the electrical operating parameters of a completed CMOS device are within an operating range comparable to CMOS devices with SiO₂ gate dielectrics. While not bound by any particular theory, it is believed that dangling, or unsaturatively coordinated Si Bonds form at the binary oxide (e.g., HfO₂) /polysilicon interface, for example due to lattice mismatch effects. By performing at least a plasma treatment, more preferably followed by an annealing treatment according to preferred embodiments, plasma implanted atoms such as hydrogen, nitrogen, and oxygen, more preferably hydrogen and/or nitrogen, penetrate and thermally diffuse to the HfO₂/polysilicon interface to passivate or bond with the dangling bonds. As a result, interface states acting as electron/hole traps are advantageously reduced thereby improving flatband and consequently threshold Voltage behavior in both PMOS and NMOS devices.

0032 For example, referring to Figure 3A, is shown a graph of exemplary data (CV curve) with capacitance on the vertical axis and applied gate Voltage on the horizontal axis in an exemplary NMOS device. Lines A, B, and C respectively represent as deposited (A), i.e., with no plasma treatment, followed by

increased times of a plasma treatment in hydrogen e.g., 30 min (B), and 60 min (C). Line D, by contrast, represents a plasma treatment followed by an annealing treatment in nitrogen (N_2) according to preferred embodiments showing a significant improvement in the CV curve characteristics including flatband Voltage derived therefrom by known methods.

0033 Referring to Figure 3B, is shown a graph of exemplary data with the flatband Voltage on the vertical axis and the gate treatment condition separated on the horizontal axis. Gate treatment condition A1 corresponds to as deposited condition (without a plasma treatment or anneal treatment); gate treatment conditions B1, C1, and D1, respectively correspond to a 10, 30, and 60 minute H_2 plasma treatment according to preferred embodiments. Gate treatment condition E1, by contrast, shows a 60 minute H_2 plasma treatment followed by an annealing treatment according to preferred embodiments, showing a significant improvement in flatband Voltage.

0034 Referring back to Figure 1, following the annealing treatment, conventional processes are then carried out to complete the CMOS device including an ion implantation process to form LDD regions e.g., 14A in the silicon substrate followed by

sidewall spacer formation e.g., 20A and a subsequent ion implantation process to form source/drain regions e.g., 14B.

0035 Referring to Figure 4 is a process flow diagram including several embodiments of the present invention. In a first process 401, an interfacial oxide layer provided over a silicon substrate. In process 403, at least one high-K dielectric layer, preferably HfO_2 , is deposited over the interfacial oxide. In process 405, a polysilicon layer is deposited. In process 407, the polysilicon layer is patterned and etched through a thickness portion of the polysilicon and high-K dielectric to form a gate structure. In process 409, a plasma treatment is carried out according to preferred embodiments. In process 411, a post plasma treatment anneal is carried out according to preferred embodiments. In process 413, conventional processes are carried out to complete the CMOS device.

0036 While the embodiments illustrated in the Figures and described above are presently preferred, it should be understood that these embodiments are offered by way of example only. The invention is not limited to a particular embodiment, but extends to various modifications, combinations, and permutations as will occur to the ordinarily skilled artisan that nevertheless fall within the scope of the appended claims.
